(54) Title: DEFLECTING TOOL INCLUDING MILLABLE OR DRILLABLE PLUG AND METHOD OF USE

(57) **Abstract:** A deflecting tool and a method to use a deflecting tool (12) in conjunction with a drilling or milling operation. The tool includes a plug (630) constructed from a millable or drillable material located intermediate the uphole and downhole ends of the tool (12). In the preferred embodiment, the plug (630) extends from proximate the uphole end of the tool towards the downhole end of the tool. Preferably, the deflecting tool (12) includes an inclined guide surface (30) which guides the milling or drilling tool (34), and the plug (630) substantially fills the volume that is at least partially defined by the inclined guide surface (30). Thus, the plug preferably completes the outer cylindrical shape of the deflecting tool (12). The plug (630) serves to ensure that at least substantially the entire face of the milling or drilling tool (34) is in contact with a millable or drillable surface throughout the length of the milling or drilling operation.

WO 01/66901 A1

## DEFLECTING TOOL INCLUDING MILLABLE OR DRILLABLE PLUG AND METHOD OF USE

### BACKGROUND OF THE INVENTION

5    **Field of Invention.** The present invention relates generally to methods and apparatus for milling windows in well casings in the downhole environment whenever the trajectory of a well should be modified after a casing or liner has been set in a well or when one or a plurality of branches are built from a parent well. More particularly, the present invention concerns a method and apparatus for milling casing windows  
10    which ensures predictable milling so that the resulting casing window will be of predetermined dimension, contour geometry, location and orientation. Even more specifically, the present invention provides for stabilized rotation and efficiently controlled guiding of a pilot mill having articulated and rotary driven relation with a substantially rigid string mill, especially during initiation of casing milling, to ensure  
15    efficient deflector controlled guiding of the pilot mill and guiding of the string mills by the pilot mill, to ensure precisely controlled formation of a casing window by the pilot mill and string mills. The present invention also concerns a casing window milling system incorporating an articulated pilot mill having the capability for controlling its amplitude of relative misalignment with a substantially rigid milling  
20    shaft and having rotary driven relation with the milling shaft during initiation of casing milling and during initial pilot boring into the subsurface formation from the casing window.

The present invention also relates to a deflecting tool that includes a plug constructed from a millable or drillable material. The plug is located on the deflecting tool so that  
25    at least substantially the entire face of an associated milling or drilling tool is in contact with a millable surface throughout the milling or drilling operation. This improves the flow of fluid from the mill or drill and increases the amount of cuttings

removed from the downhole environment. The plug may also be used to fill in gaps or spaces within downhole tools that may have to be milled while located in the downhole environment.

**Related Art.** Casing windows are required whenever the trajectory of a well should  
5 be modified after a casing or a liner has been set in a well or when one or a plurality of branches are built from a parent well.

A casing window is generally performed with a combination of mills mounted on a mandrel at the bottom end of a drill string and wedging between the casing and a deflection tool called the whipstock. The whipstock is generally set in the hole in  
10 combination with the first milling run. The window may be completed in one single operation in the hole or in multiple runs. The peripheral surface of mills is generally covered with abrasive or cutting inserts made of hard material such as sintered tungsten carbide compounds brased on a steel mandrel. The hardness of the  
15 whipstock is generally designed so minimum wear will be generated by the rotation of mills peripheral surface onto the whipstock face while the assembly is pushed and rotated against the casing wall under deflecting action of the whipstock. However the milling action generally results from unbalanced pressures between respectively the mill(s) and the whipstock on one hand and the mill(s) and the casing wall on the other hand.

20 In high inclination condition, the whipstock face is generally oriented upward and therefore forces applied by the mill(s) onto the whipstock face increase with the increasing weight component of the milling string. Although a whipstock is expected to support some milling damage, how much whipstock material is left after milling has been preformed is difficult to predict. In such case the success of whipstock  
25 retrieval may become risky and lead to lost time and additional contingency and sometimes to the loss of the bottom section of the well.

The lack of control on the window geometry is another major disadvantage of conventional window milling techniques and makes some lateral branching techniques inapplicable or more complex. Most windows show a lower section directed sideways with respect to the hole axis. How much this “walk away” affects a window is hardly predicable and depends on several factors like well inclination, pilot mill size and shape, mill cutting structure, weight on bottom hole assembly, whipstock hardness and orientation.

When the formation surrounding the well casing being penetrated by the window bore is well consolidated, it is desirable that the pilot mill have a geometry enabling it to be efficiently guided along an intended trajectory by the wall surface of the wellbore being formed. When the formation surrounding the wellbore is not well consolidated, a pilot mill which has a freely articulated and rotary driven connection with a substantially rigid milling shaft could be subject to forces that might tend to change its course from the intended trajectory. If the pilot mill should be suddenly articulated when encountering some unusual structure in the downhole environment, the pilot mill or its articulated connection with the milling shaft could become damaged, perhaps to the extent of being separated from the milling shaft. It is desirable therefore to provide a casing window milling system having an articulated pilot mill and also having a mechanism for controlling the amplitude of relative misalignment of the pilot mill relative to the axis of rotation of the milling shaft. This pilot mill amplitude control feature will permit the pilot mill to be efficiently deflected so as to follow the slope of the deflecting tool without damaging the deflecting tool and will permit the pilot mill to be constrained in a coaxial relationship with the milling shaft so as to be guided by the milling shaft after the pilot mill has passed a point on the deflecting tool where self guiding of the pilot mill can no longer be ensured. Thus it is desirable to provide a casing window milling tool which incorporates a locking or restraining mechanism which can be actuated mechanically or hydraulically to lock the pilot mill in co-axial, stabilized relation with the milling shaft.

During the initial stages of a milling or drilling operation, only a portion of the face of the relevant milling or drilling tool contacts a millable or drillable surface (the target casing), allowing a large number of cuttings to fall down the wellbore and/or be forced down the wellbore by hydraulic fluid jetting from the mill. Many of the cuttings that fall lodge proximate the downhole end of the deflecting tool 12 (or possibly farther down) and become an obstruction that must be removed prior to the commencement of post-milling or -drilling operations. Such removal is typically performed at a high cost. Therefore it is desirable to provide an apparatus and method that can increase the amount of cuttings that are removed from the downhole environment during a milling or drilling operation. It is also desirable to provide an apparatus and method that improves the flow of fluid from the milling or drilling tool.

### SUMMARY

It is a primary feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows which employs a rotary milling tool having an articulated pilot mill provided with cutting means only on its forward axial end so that the pilot mill is capable of cutting only on the forward axial end thereof and will not cut or substantially erode away a deflection element that is utilized to guide the pilot cutter;

It is another feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows which utilizes an articulated pilot mill not only for pilot hole cutting but also for efficiently guiding other milling cutters of the apparatus during milling activities so that the geometry and location of the resulting casing window will conform specifically to plan and will not be varied by other factors during milling;

It is also a feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows which employs guide means such as a

tubular guide bearing to render the pilot mill extremely stable during initial forming of the casing window;

It is another feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows which utilizes an articulated pilot mill  
5 having a non-milling periphery for guided engagement with an inclined guide surface of a deflecting device and having a forward milling end for milling a pilot window bore through the well casing and into the surrounding formation;

It is also a feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows wherein a pilot mill is employed which has  
10 articulated driven connection with a substantially rigid string mill and which is adapted for non-milling engagement with an inclined guide surface and is adapted for pilot window milling engagement with the casing of a well;

It is a feature of the present invention to provide a well casing milling system incorporating a pilot mill having articulated driven connection with a substantially  
15 rigid string mill shaft wherein the articulated driven connection comprises a universal joint which transmits torque and axial load from the substantially rigid string mill shaft to the pilot mill;

It is also a feature of the present invention to provide a novel casing window milling system having a pilot mill that has articulated rotary driven connection with a  
20 substantially rigid milling shaft by means of a universal joint and wherein the universal joint incorporates an articulation control mechanism for adjusting the amplitude of angular misalignment of the pilot mill relative to the milling shaft between a maximum allowable angle and a coaxial relationship and for locking the pilot mill at the selected amplitude of angular misalignment;

It is another feature of the present invention to provide a well casing milling system incorporating a pilot mill and a substantially rigid string mill shaft and means for decoupling the bending moment that would otherwise be transmitted between the pilot mill and string mill shaft as the pilot mill is diverted from the longitudinal axis of the well casing to the inclined path of the guide surface of the deflector tool;

It is an even further feature of the present invention to provide a well casing milling system incorporating a deflecting tool having an upper guide bearing to provide an articulated rotary driven pilot mill of a milling assembly with precise guiding during initial casing window milling to ensure rotary stabilization of the pilot mill and ensure proper orientation and direction of the pilot bore;

It is a feature of the present invention to provide a well casing milling system incorporating a pilot mill having articulated driven connection with a substantially rigid string mill shaft and wherein the articulated rotary driving connection defines a flow passage through which a suitable fluid may be pumped for cooling or otherwise enhancing the casing window milling operation;

It is a feature of the present invention to provide a well casing milling system incorporating a pilot mill having articulated driven connection with a substantially rigid string mill shaft and wherein the pilot mill defines a non-milling substantially cylindrical guiding periphery and the articulated rotary driving connection defines the axis of rotation of the pilot mill and is located within and intermediate the axial length of the pilot mill to provide for stability and guidance thereof;

It is another feature of the present invention to provide a well casing milling system incorporating a deflecting tool which is set within the well casing and which defines an inclined guide surface for non-milling engagement by an articulated pilot mill of a casing window milling assembly and which deflecting tool defines a passage through which fluid may be caused to circulate and well tools may be passed for conducting

other well activities with the deflecting tool in place or for retrieval of the deflecting tool from the well casing;

It is a feature of the present invention to provide a well casing milling system incorporating a pilot mill having articulated driven connection with a substantially rigid string mill shaft and employing a rotary drive means having articulated driving  
5 connection with the substantially rigid string mill shaft, which rotary drive means may take the form of a positive displacement motor, turbine or other equivalent power source and which rotary drive means may be rotated by a drill string for enhancing the power and/or speed of the milling system;

10 It is another feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows and has a pilot mill which has articulated driven connection with a substantially rigid milling shaft having string mills and which provides radial force to the rigid shaft and string mills causing the string mills to penetrate into the casing without substantial wear of the guide face of the deflection  
15 tool;

It is also a feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows which incorporates a deflecting tool which is set within the well casing and a milling assembly having a substantially rigid milling shaft and a pilot mill having articulated rotary driven connection with the  
20 milling shaft and wherein the milling assembly and the deflection tool may be releasably interconnected during running operations to ensure single pass installation and desired initial relative positioning of both the deflecting tool and milling assembly before the casing window milling operation is initiated;

It is an even further feature of the present invention to provide a novel method and  
25 apparatus for predictable milling of casing windows which employs an elongate milling tool having sufficient stiffness to prevent or minimize its deflection during

milling so that the resulting casing window will have precisely and predictably determined characteristics of window dimension, window contour geometry and location;

It is also a feature of the present invention to provide a novel method and apparatus  
5 for predictable milling of casing windows which employs deflection tool establishing a substantially tubular pilot mill guide or pilot mill and rotary drive motor guide for guiding the articulated pilot of the window milling tool and wherein a portion of the tubular pilot guide is partially milled by succeeding window mills to form the deflecting tool with a predictable guide surface geometry that is suitable for guiding  
10 well tools from the main well bore through a casing window and into a lateral bore; and

It is an even further feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows which incorporates a deflecting tool and milling tool which enable guided movement of the milling tool and its rotary  
15 drive motor and rotary stabilizer within a guide passage of the deflecting tool; and

It is also a feature of the present invention to provide a novel method and apparatus for predictable milling of casing windows which is design to enable a deflecting tool and a casing window milling tool to be run into a well casing as a unitary assembly and after milling of a casing window, to be extracted from the well casing as an  
20 assembly.

It is also a feature of this invention to provide an apparatus and method that can increase the amount of cuttings that are removed from the downhole environment during a milling or drilling operation.

It is also a feature of this invention to provide an apparatus and method that improves  
25 the flow of fluid from the milling or drilling tool.

Briefly, a downhole casing window milling assembly embodying the principles of the present invention is composed of a rotary positive displacement motor, a hollow rotary driving articulation connected to the motor bit box on its upper end and to a substantially rigid milling shaft on its lower end, a pilot mill having articulated  
5 connection with the substantially rigid milling shaft, a deflection tool releasably connected to the bottom of the milling tool and an anchoring device at the very bottom which additionally provides for location and orientation of the casing window milling system within the well casing.

The rotary positive displacement motor drives the milling assembly through an  
10 articulated joint such as a universal joint or a short flex joint which also defines a flow passage. The purpose of such articulation or short flex joint is to decouple, cancel or minimize bending moments that could be transmitted by the milling assembly to the motor bearings while still allowing fluid to circulate to the bottom of the milling assembly. If desired, the rotary drive motor can eventually include two power  
15 sections to provide additional torque without creating additional conveyance constraints in high dog leg severity wells.

The downhole motor can be also a turbine or other alternative downhole rotary power generation wherever the mechanical power source will be most appropriate without noticeably affecting the basic benefit of the milling equipment. The downhole motor  
20 and its rotational stabilizer can also be adapted for passing through the deflecting tool and to be guided by the deflecting tool when the deflecting tool incorporates a tubular guide.

Although use of downhole rotating power source such as positive displacement motors provide better milling performance in deviated or horizontal wells, the bottom  
25 milling tool may be alternatively powered by or in combination with a conventional rotary drill string. While using a downhole power source, the drill string may be rotated to provide additional mechanical power to the milling tool and also to

minimize the effect of dragging forces and thus provide better control of milling tool penetration.

The casing window milling assembly is composed of a plurality of string mills mounted on a substantially rigid hollow milling shaft. A pilot mill is mounted for articulation at the bottom end of the milling shaft and is rotated and moved axially by the milling shaft. The pilot mill is of generally cylindrical configuration and defines a generally cylindrical outer peripheral surface which establishes a non-milling, guided relationship with the inclined guide surface of the deflecting tool. The pilot mill has a milling face only at its forward end and has no abrasive material on its outer periphery so that the deflecting tool is not subject to significant milling action by the pilot mill as the pilot mill is rotated and guided during window milling. The pilot mill is articulated within a small angular amplitude relative to the milling shaft so it can spin along an axis parallel to the inclined guide face of the deflection tool and be guided without milling the guide face of the deflection tool, unlike conventional casing window milling tools which typically having milling contact with the deflection tool and thus tend to remove at least a portion of the guide face during milling. The milling shaft is provided with at least one and preferably two or more string mills, such as a gauging mill and a reaming mill, for example, which are each typically of greater diameter than the diameter of the pilot mill. The initial string mill is mounted to the milling shaft at a relatively short distance from the pilot mill so most of the opening milled in the well casing will be made with the initial string mill. Optionally, one or several reaming mills can also be mounted on the milling shaft above the first string mill. In most common situations, casing windows are of full size, meaning that the diameter of a cylinder passing through the window is substantially equal to the casing inside diameter. In this case the outside diameter of the pilot mill is smaller than that of the string mill(s) which typically have a diameter that is very close to the drift diameter of the casing. The milling system can incorporate a locking or restraining mechanism for controlling the amplitude of misalignment of the pilot mill relative to the milling shaft from a coaxial relationship

to a relationship permitting a maximum degree of allowable articulation. This feature permits the pilot mill to be efficiently guided along the slope of the deflecting tool or whipstock during initial casing window milling and permits guiding of the pilot mill to be controlled by the milling shaft when the pilot mill has moved along the guiding  
5 face of the whipstock to a point that its efficient self guiding can no longer be ensured. In one suitable form the locking or restraining system may take the form of a hydraulic piston actuated mechanism which is maintained in a release position by captured hydraulic fluid within a closed chamber. The hydraulic fluid may be released in any suitable manner, such as by breaking of a frangible element or by pressure responsive  
10 opening of a release valve to permit spring urged movement of the hydraulic piston to a position causing restraint or locking of the articulated connection between the pilot mill and the milling shaft. When so restrained, the pilot mill will be guided along the intended trajectory by its coaxial or axial misalignment controlled relation with the milling shaft and with its trajectory being controlled by the milling shaft. Moreover,  
15 under conditions where unusual forces are encountered that might tend to deflect the pilot mill from its intended course the locking or restraining mechanism will ensure that the pilot mill will maintain its intended trajectory.

In the case of undersize windows, meaning that the diameter of a cylinder passing through the window is substantially smaller than the casing inside diameter, the  
20 diameter of the pilot mill may be equal to the diameter of the string mills. This is generally the case of window milling in a production liner/casing which requires the milling tool to be passed through a production tubing.

The invention also provides a deflecting tool and a method to use a deflecting tool in conjunction with a drilling or milling operation. The tool includes a plug constructed  
25 from a millable or drillable material located intermediate the uphole and downhole ends of the tool. In the preferred embodiment, the plug extends from proximate the uphole end of the tool towards the downhole end of the tool. Preferably, the deflecting tool includes an inclined guide surface which guides the milling or drilling tool, and the plug substantially fills the volume that is at least partially defined by the

inclined guide surface. Thus, the plug preferably completes the outer cylindrical shape of the deflecting tool. The plug serves to ensure that at least substantially the entire face of the milling or drilling tool is in contact with a millable or drillable surface throughout the length of the milling or drilling operation thereby improving the flow of fluid from the mill and increasing the amount of cuttings removed from the downhole environment. The plug may also be used to fill empty spaces or gaps of downhole tools that may have to be milled while located in the downhole environment.

### BRIEF DESCRIPTION OF THE DRAWINGS

- 10 So that the manner in which the above recited features, advantages and objects of the present invention are attained and can be understood in detail, a more particular description of the invention, briefly summarized above, may be had by reference to the preferred embodiment thereof which is illustrated in the appended drawings, which drawings are incorporated as a part hereof.
- 15 It is to be noted however, that the appended drawings illustrate only a typical embodiment of this invention and are therefore not to be considered limiting of its scope, for the invention may admit to other equally effective embodiments.

## DETAILED DESCRIPTION OF THE INVENTION

- 20 Referring now to the drawings and first to Figs. 1 and 2, a downhole casing window milling assembly constructed in accordance with the principles of the present invention and representing the preferred embodiment of the present invention is shown generally at 10. The casing window milling assembly 10 is comprised of deflecting tool shown generally at 12, and a milling tool shown generally at 14 and  
25 rotary drive motor assembly shown generally at 16.

The deflecting tool 10 is defined by an elongate deflecting body 18 which is adapted to be run into the main well casing and to be precisely located and oriented for milling

of a casing window. The deflecting tool 18 may define a longitudinal passage 20 through which fluid may be caused to flow and through which certain downhole well operations may be conducted. The longitudinal passage 20 will not interfere with deflection of the window milling system during milling operations because, as will be explained in detail hereinbelow, the window milling string of the milling tool will be caused to precisely traverse a predetermined trajectory to ensure generation of a guide surface of predetermined configuration on the deflecting body as the milling tool is deflected from the longitudinal axis of the well casing and progresses along a predetermined inclined path through the wall of the well casing. The longitudinal passage 20 will also accommodate a suitably sized spear fishing tool without compromising the guiding and performance of the deflecting tool. This feature enables simple and efficient removal of the deflecting tool from the well casing. The longitudinal passage 20, if desired, may be initially filled with a drillable material which is easily removed with the deflecting tool set within the well casing in the event the fluid flow or retrievable characteristics of the deflecting tool are needed. The deflecting tool 12 may also define a connection geometry to provide efficiently for connection thereof to a retrieval device that is run into the well casing for connection to and retrieval of the deflecting tool 12 subsequent to the window milling operation.

At its lower or forward end the elongate deflecting body 18 defines a connector shown generally at 22 which enables connection of various other well equipment such as an anchor, bridge plug, selective landing tool or other means that positively secure the deflection tool in the well casing. The connector 22 may take the form of a connection receptacle 24 into which a connecting section of other well equipment is received. Connection may be established by a releasable connector element 26 or by any other suitable means. Orientation of the deflecting tool 12 with respect to the well casing may be established in any suitable manner. For example, the well casing may be provided with an orienting coupling within which is located an orienting slot or an orienting key of conventional nature. The deflecting tool or any other apparatus to which the deflecting tool is connected may be provided with a corresponding orienting

feature for orienting engagement with the orienting slot or key to thus provide for precise location and orientation of the deflecting tool with respect to the well casing. In the alternative, for well casings without indexing or orienting features, an indexing packer may be set in suitably located and oriented relation within a well casing and the  
5 diverting tool may be landed and set with respect to the orienting and indexing feature of the indexing packer.

At its upper or trailing end the deflecting tool 12 is provided with a pilot mill guide which defines a contoured and inclined guide surface 30 representing the primary inclined guide surface of the deflecting tool. As is evident from the transverse  
10 sectional view of Fig. 6, taken along line 6-6 of Fig. 3, the contoured inclined guide surface 30 may initially be of partially cylindrical or curved cross-sectional configuration so that it defines an elongate inclined guide groove or slot which diverts a forwardly moving milling assembly from the longitudinal axis of the main well bore to the desired exit angle for a lateral bore.

15 Conventionally, when the initial milling element of a casing window milling assembly comes into contact with a deflecting tool, also identified as a whip-stock, significant lateral force is imparted both to the whip-stock and to the initial milling element. This typically results in significant removal of material forming the guide surface of the whip-stock and results in significant application of bending or deflecting force to the  
20 milling tool and its rotary drive mechanism. Since most conventional casing window milling tools are diverted but not significantly guided, the milling tool will tend to wander during window milling so that the casing window formed by the milling operation is typically imprecise from the standpoint of location, orientation, window size and contour geometry. To overcome this disadvantage it is considered desirable  
25 to ensure precision guiding and controlled orientation of the milling assembly especially during initial milling contact with the well casing. According to the principles of the present invention this precision milling tool guiding feature is accomplished by providing the deflecting tool with a guiding and stabilizing feature

for ensuring the accuracy of milling tool tracking during milling. The precision milling feature is also enhanced by eliminating or significantly minimizing application of lateral forces to the deflecting tool and to the milling assembly. To ensure the accuracy of orientation, location, dimension of the contour geometry of the casing window being milled it is necessary to establish precision guiding and stabilization of the initial milling element at the outset of the milling operation. To accomplish this initial guiding and stabilization feature the elongate body 18 of the deflecting tool 12 is defined in part by a guide bearing 32 of generally tubular geometry which defines a generally cylindrical internal guide surface 33 which may form a part of the inclined guide surface or face 30. Thus the inclined contoured guide surface 30 is in part of cylindrical configuration so as to define a pilot mill guide surface that is oriented along a predetermined inclination relative to the longitudinal axis of the well casing that establishes a predetermined lateral bore trajectory to be followed by milling apparatus for milling a casing window of predictable dimension and contour geometry and to establish the trajectory of a lateral wellbore which is subsequently drilled along the trajectory that is established by window milling equipment.

The milling tool shown generally at 14 incorporates a pilot mill 34 which has a substantially cylindrical outer guided periphery 36 defined by a plurality of lands 38 that are separated by fluid transfer channels 40. The lands 38 are defined by cylindrical surface segments which establish non-milling guided relation with the internal cylindrical surface 30 of the guide bearing 32 and after moving past the guide bearing, establish non-milling guided relation with the inclined, contoured guiding face 30 of the deflecting tool. The internal cylindrical guide surface 33 of the guide bearing 32 ensures that the pilot mill is precisely confined to its intended trajectory and ensures precision milling of a pilot bore through the well casing and into the formation surrounding the casing. Since only the non-milling cylindrical guided surface of the pilot mill 34 will contact the internal cylindrical surface 33 of the guide bearing 32 or the inclined guide surface 30, the inclined contoured guide surface will not be eroded to any significant extent by the pilot mill 34 and thus will remain after

completion of the milling operation has been completed to serve as a guide surface for guiding other well tools through the casing window and into the lateral bore.

As the pilot mill 34 is diverted from the longitudinal axis of the main well casing to the trajectory of the branch bore it is desirable that no significant lateral forces be imparted either to the pilot mill 34 or to the diverting tool 12. It is also desirable that the pilot mill 34 have an efficiently guided and stabilized relationship with the internal cylindrical guiding surface of the guide bearing 32 as milling of the casing is initiated. It is considered desirable therefore to provide the pilot mill 34 with pivotally articulated connection with a relative to a substantially rigid milling shaft, to be discussed in detail hereinbelow, and to locate its point of pivotal articulation internally and intermediate the length of the pilot mill. This feature will enable the pilot mill 34 to be readily pivoted so that it will precisely track the angular inclination defined by the internal generally cylindrical surface 33 of the guide bearing 32.

Referring now particularly to Figs. 11 and 12 the pilot mill 34 has a mill head structure 35 from which extends an elongate generally cylindrical mill body 37. The mill body 37 defines an internal connection receptacle 42 within which is seated a pair of universal joint inserts 44 and 46 being secured in fixed relation within the connection receptacle 42 of the pilot mill structure by connection pins 48 and 50 which are welded as shown or otherwise fixed to the pilot mill structure. The connection pins 48 and 50 are received within connection pin receptacles that are defined respectively within the universal joint inserts 44 and 46 as shown in Fig. 11. It is to be borne in mind that the universal joint inserts may be fixed within the connection receptacle 42 by any other suitable means, such as by welding or by machining partially spherical surface segments within the mill body 37. The universal joint inserts 44 and 46 further define internal spherical surface segments 52 and 54 which, when the inserts are positioned in assembly as shown in Fig. 11, cooperatively define a spherical receptacle 56 within which is retained a spherical universal joint

element 58 defining a part of the forward end 60 of an elongate tubular milling shaft 62.

To maintain a non-rotatable relationship and to provide for torque transmission between the milling shaft 62 and the pilot mill 34 and to also permit articulation of the pilot mill relative to the elongate milling shaft the universal joint receptacles 44 and 5 46 also define ball receptacle segments 64 and 66 respectively. The ball receptacle segments 64 and 66 cooperate with a plurality of ball receptacle segments 68 to define a plurality of ball receptacles 70 each receiving a torque transmitting ball 72. The ball 10 receptacles 70 are of greater dimension than the dimension of the torque transmitting balls as shown in Fig. 11 to thereby permit the pilot mill 34 to have the capability for pivotal articulation relative to the milling shaft 62. The looseness of fit of the torque transmitting balls 72 with their respective ball receptacles permits movement of the pilot mill 34 about a point P located on the longitudinal axis 74 of the elongate milling shaft. This feature permits the pilot mill to maintain a predetermined inclination with 15 respect to the longitudinal axis of the milling shaft 62 as the pilot mill is rotated by the milling shaft. This feature also permits efficient guiding of the pilot mill by the inclined guiding features of the diverting tool without imparting significant lateral force to the diverting tool or bending moment to the substantially rigid milling shaft 62.

20 The head structure 35 of the pilot mill 34 also defines a circular tapered milling face 76 which intersects with a flat, circular, centrally located mill nose 78. The milling face and mill nose is provided with any suitable means for milling or eroding the well casing to define a pilot window opening therein. It should be borne in mind that the cylindrical outer periphery 36 of the pilot mill 34 is not provided with milling or 25 cutting elements or materials so that milling of the well casing occurs only when the end face 76 of the pilot mill 34 is moved into contact with the well casing as the pilot mill is rotated by the milling shaft 62 via the universal joint interconnecting the pilot mill 34 with the milling shaft. The end face and mill nose of the pilot mill 34 is

coated with adequate abrasive inserts such as tungsten carbide compound or other suitable abrasive materials that are utilized on casing window mills. The abrasive milling material may be brazed or otherwise fixed to the face surface of the pilot mill and to the surfaces of string mills that follow the pilot mill. Thus, the pilot mill 34 is  
5 capable of milling only when its end face 76 is in contact with the well casing. Contact by the outer peripheral surface 36 of the pilot mill with the well casing, the deflecting tool or any other structural object will not cause erosive wear thereof. The outer cylindrical surface 36 of the pilot mill 34 is intended only for guide purposes to guide the pilot mill along an intended inclined trajectory with respect to the  
10 longitudinal axis of the well casing so as to perform a pilot opening in the well casing.

To enhance milling of the well casing by the pilot mill 34, the pilot mill defines a plurality of fluid circulation passages 80 which are disposed in communication with a circulation fluid supply manifold passage 82. The manifold passage 82 receives circulation fluid from a fluid supply passage 84 of the elongate tubular milling shaft  
15 62. Thus, the universal joint additionally serves for fluid flow transmission between the tubular milling shaft and the pilot mill 34. The milling end face 76 of the pilot mill 34 also defines fluid circulation channels 86 which transport the circulation fluid medium from the circulation passages 80 to the side channels 40 of the pilot mill. Although the lands 38 and the side channels 40 of the pilot mill are shown to be of  
20 helical configuration in Fig. 3 to enhance circulation flow as the pilot mill is rotated, it should be borne in mind that the lands and side channels may be of any other configuration, such as substantially straight and parallel, without departing from the spirit and scope of the present invention. To ensure against fouling of the universal joint by debris such as particulate milled from the well casing or from the surrounding  
25 formation the internal connection receptacle 42 may be provided with a seal assembly 43, such as a bellows seal for example, for excluding any such debris from the universal joint. In addition to providing a seal between the pilot mill 34 and the milling shaft 62, the seal 43 must also accommodate the pivotal articulation of the pilot mill relative to the milling shaft.

Referring now again to Figs. 1 and 2 the elongate tubular milling shaft 62 is substantially rigid and is provided with at least one milling element 88 and preferably a plurality of string milling elements or mills 88 and 90 which are fixed in spaced relation along the length of the milling shaft. Although two milling elements 88 and 90 are shown it should be borne in mind that any number of milling elements may be located along the length of the milling shaft 62. The initial string mill is located quite close to the pilot mill so that most of the window opening that is milled within the well casing is formed by the initial string mill. The mill 88, or the first of the string mills 88 and 90, will typically have a diameter exceeding the diameter of the pilot mill 34. In this case the first string mill 88 will be a gauging mill which greatly enlarges the much smaller pilot mill bore to roughly the desired diameter necessary for a casing window of predetermined dimension and contour geometry. The second of the string mills, mill 90, will typically be a reaming mill which finalizes the dimension and contour geometry of the window being milled in the well casing. The diameter of the string mills is typically very close to the drift diameter of the well casing. The string mills 88 and 90 each define a plurality of abrasive covered lands 92 and fluid circulation channels 94 to provide for milling of the well casing and to permit fluid circulation past the string mills during milling activities. If desired, the fluid circulation channels of the string mills may be provided with a flow of fluid from the internal passage 84 of the milling shaft 62 to thus provide for cooling of the string mills and for removal of milled particulate and other debris as a window milling operation is in progress.

In the case of undersized casing windows, meaning that the diameter of a cylinder passing through the window is substantially smaller than the casing inside diameter, the diameter of the pilot mill 34 and the string mills 88 and 90 may be of equal diameter. This is generally the case of a window milling operation in a production liner/casing having the requirement that the milling tool must pass through a production tubing string.

As the casing window milling operation progresses the orientation of the milling shaft 62 will be translated from a coaxial relation to an inclined relation with the longitudinal axis of the main wellbore as shown by angle "d" in Fig. 8. It is desirable that the rotary drive means of the casing milling system be isolated or decoupled from any lateral forces or bending moments that might cause exceptional wear of the bearings of the rotary drive mechanism. At its trailing or upper end the elongate tubular milling shaft 62 is provided with an articulating connection shown generally at 96. This articulating connection may be of substantially identical construction and function, as compared to the universal joint mechanism of Fig. 11, which establishes articulating connection of the pilot mill 34 to the forward end 60 of the milling shaft 62. The articulating connection 96 is established by a spherical end 98 of the milling shaft which is captured by universal joint inserts 100 and 102 in the same manner as discussed above in connection with the universal joint of Fig. 11.

Driving rotation between the universal joint 96 and the elongate milling shaft 62 is defined by a plurality of torque transmitting ball elements 104 which are loosely received within ball receptacles in the same manner and for the same purpose as described above. The universal joint connection 96 also defines a flow passage such as shown at 84 in Fig 11 to permit the flow of circulation fluid into the milling shaft passage 84 from the drill string to which the rotary drive mechanism is connected. The universal joint connection at the forward end of the milling shaft 62 with the pilot mill 34 and the universal joint connection 96 at the trailing end of the milling shaft permits orientation of the milling shaft at any point in time to be established jointly by its forward and trailing universal joint connections. Moreover, the elongate tubular milling shaft 62 is substantially rigid and is decoupled from both the pilot mill and the rotary drive mechanism by its universal joint connections so that it is not deflected significantly by any of the forces to which it is subjected during milling operations. The rigidity of the milling shaft causes the string mills 88 and 90 to be efficiently guided by the pilot mill as the pilot mill 34 is guided along its intended trajectory by the inclined guide surface 30 of the body structure 18 of the deflecting tool 12. Since

the milling shaft is oriented by the positions of its universal joints, the string mills do not remain concentric with the pilot mill or with the universal joint connection thereof with the rotary drive mechanism. This feature causes the string mills to have controlled milling relation with the primary inclined guiding feature 30 of the body structure 18 of the deflecting tool 12 as shown by Fig. 2 and as shown in the operational views of Figs. 9 and 10. Thus, the string mills change a portion of the primary inclined guide surface during milling so that a predetermined contoured guide surface will remain after completion of the window milling operation to serve as a contoured guiding face for well equipment that is run into the well casing and diverted through the casing window and into the lateral bore.

For rotation of the milling shaft 62 the universal joint 96 for driving and permitting articulation of the milling shaft is provided with a threaded pin type pipe connection 106 which is received by the internally threaded box connection 108 of the rotary output shaft of the rotary drive assembly 16. The rotary drive assembly 16 incorporates a rotary drive motor 110 which is positioned by a drill string extended from the surface through the well casing. It should be borne in mind that rotary drive motor 110 may take any number of suitable forms without departing from the spirit and scope of the present invention. For example, the rotary drive motor may conveniently take the form of a rotary positive displacement motor or a turbine which is driven by the flow of a fluid medium being pumped through the drill string to the rotary motor. The rotary drive motor 110 may also be powered by a mud motor that is connected at the lower end of a drill string extending from the surface. The drill string may be fixed during window milling operations or in the alternative, it may be rotated at a suitable rotary speed to provide for operation of the casing window milling assembly. Additionally, a rotary drill string may be utilized in combination with a rotary positive displacement motor, turbine or the like for achieving desired rotary speed and torque of the elongate milling shaft to provide for optimum window milling.

It is well known that rotary apparatus such as a fluid energized motor, rotary drill string etc. are rotated within a well casing, the rotary apparatus tends to oscillate or otherwise become unstable within the well casing. To ensure that no extraneous oscillation is transmitted to the milling tool 14 by the rotary drive motor, a stabilizer  
5 112 is connected between the drive motor 110 and the connection box 108. Thus, as it is rotatably driven the upper or trailing end of the elongate tubular milling shaft 62 is stabilized by the stabilizer element 112 and thus remains essentially free of vibration which might otherwise contribute to inaccuracy of casing window milling. As is typical with stabilizers, the stabilizer 112 is provided with lands and fluid  
10 circulation channels as shown.

Referring now again to Figs. 3, 6, and 7 the casing window milling assembly 10 may be inserted into the well casing as a unitary or integrated assembly. This is accomplished by positioning releasable fasteners such as shear screws 113 and 114 in the tubular guide bearing 28 so as to resist both rotary and linear motion of the pilot  
15 mill 34 and the milling shaft 62 relative to the deflecting tool 12. The shear strength of the shear screws 113 and 114 is sufficient to maintain the fixed relation of the pilot mill 34 within the tubular bearing 32 and to support the deflecting tool 12 as the casing window milling assembly 10 is inserted into and set with respect to the well casing. This feature permits both the deflecting tool 12 and the milling tool 14 to be  
20 properly positioned within the well casing in a single pass running operation. After the deflecting tool 12 has been properly oriented and set within the well casing, with the milling assembly fixed thereto by fastening means, milling operations may be initiated by applying sufficient rotational force to the pilot mill 34 by the milling shaft 62 to cause shearing of the shear screws 113 and 114. After this has been  
25 accomplished the pilot mill 34 is then free of the tubular bearing and may be rotated and moved linearly toward the well casing wall as it is guided initially by the internal cylindrical surface of the guide bearing 32 and then by the inclined contoured guide surface 30 of the elongate deflecting tool body 18 of the deflecting tool 12. This feature enables the pilot mill 34 to form a pilot bore along the intended inclined

trajectory established by the tubular bearing 32 and the inclined guide surface 30 and to cause precision milling of a pilot window in the well casing and a precisely oriented and located pilot bore into the immediately surrounding structure, i.e. casing cement and formation material as is evident from Figs. 2, 9 and 10.

## 5 OPERATION

Preferably the deflecting tool and the milling tool are run into the well casing as an integral unit, so that casing window milling can be initiated by a single pass installation. In this case the shear screws 113 and 114 will maintain the milling tool in releasable assembly with the deflecting and will maintain the pilot mill 34 secured  
10 within the pilot mill bearing 28 essentially as shown in Figs. 3 and 6. To release the pilot mill for milling rotation a suitable force is applied either by rotating the milling shaft and pilot mill with the rotary power source 110 or by imparting a linear force to the milling shaft. After the casing window milling assembly 10 has been located within the well casing with the deflecting tool being oriented and fixed within the well  
15 casing and the pilot mill 34 rendered rotatable as the result of shearing the shear screws 113 and 114 or otherwise releasing suitable fastener means, the elongate milling shaft 62 is rotatably driven by the rotary drive means 110 and linear movement of the milling tool 14 is initiated. As the pilot mill 34 is rotated and moved linearly during the initial stage of casing window milling it is rendered highly stable  
20 by the tubular guide bearing section of the deflecting tool 12. Since the pilot mill 34 is of essentially cylindrical configuration and is initially rotated within the substantially cylindrical internal surface of the guide bearing 32 it is simply and efficiently self guided and stabilized by the tubular guide bearing 32 and precisely oriented for milling a pilot opening of accurately controlled location, orientation and  
25 contour geometry in the well casing. This self guiding and stabilizing feature of the pilot mill 34 is enabled by locating the articulation pivot point of the pilot mill internally thereof and intermediate its axial length and along its axis of rotation. Stabilization of the pilot mill 34 in this manner enables the pilot mill to initiate

window milling of the well casing and to generate a precisely controlled pilot bore which provides for guiding milling shaft 62 and its gauging and reaming mills 88 and 90. As mentioned above, the articulating connection of the pilot mill with the forward end of the milling shaft and the articulated connection of the trailing end of the milling shaft with the bit box connection of the rotary drive means and stabilizer assembly results in stabilized rotation and orientation as well as precision guiding of the milling shaft 62 at both of its ends. Since the milling shaft 62 is substantially rigid, this double ended articulation of the milling shaft causes its progressive orientation as the pilot mill 34 continues milling a pilot bore of inclined trajectory through the well casing and into the surrounding formation, with orientation of the pilot bore being determined by the inclination of the internal cylindrical guide surface guide surface 30 of the deflecting tool 12. Immediately as the forward end of the pilot mill 34 is projected from the tubular guiding and stabilizing surface of the tubular guide bearing 32 the inclined trajectory of the pilot mill 34 and its articulating connection with the forward end of the milling shaft 62 will cause the milling end face 76 of the pilot mill to engage and begin milling a pilot window opening in the well casing. Simultaneously, as shown particularly in Fig. 2 the inclined trajectory of the pilot mill 34, through its articulated connection with the milling shaft 62 causes the gauging and reaming milling elements 88 and 90 to be maintained in controlled relation with the inclined guide surface of the deflecting tool. This causes the string mills 88 and 90 to enlarge and finalize the pilot window in the well casing and to establish the initial inclination of an inclined lateral bore while at the same time having controlled guide surface forming relation with the elongate body 18 of the deflecting tool 12. It should also be noted that the guided relation of the pilot mill 34 with the tubular bearing structure 32 and the inclined contoured guide face 30 causes the string mills 88 and 90 to be directed into milling contact with a sacrificial portion 41 of the tubular bearing structure 32 which is shown in Fig. 6 and is shown to have been removed in Fig. 7. When the pilot mill 34 is located within the tubular guide bearing 32 the appearance of the tubular guide bearing will be as shown in Fig. 6. After the milling operation has been completed the string mills 88 and 90 will have

milled away a sacrificial portion of the tubular guide bearing 32, leaving an open guiding face 116 that is defined by curved lateral segments 118 and 120 having an intermediate curved guide surface segment 122 which is located between the curved guide surface segments 118 and 120 and which is defined by the original cylindrical configuration of the internal guide bearing surface 30. After the milling operation has been completed the open guiding face 116 will serve as a deflecting guide surface for guiding various well tools into the lateral branch.

As shown by the transverse sectional views of Figs. 4 and 5, both taken along line 4-4 of Fig. 3, the transverse geometry of the deflecting tool body 18 will have the configuration shown in Fig. 4 before the casing window has been milled. In the region of the section line 4-4 the deflecting body 18 will define an open guiding face 124 which is defined by a substantially cylindrical guiding surface which intersects the flow passage 20 and also intersects the outer peripheral surface 126 of the deflecting tool at 128 and 130 and thus defines an open guide face or slot 132. After the milling operation has been completed the sacrificial region 41 of the tubular guide bearing 32 and the deflecting body 18 will have been removed, leaving an open contoured guiding face 134. The contoured open guiding face 134 is defined in part by guide surface segments 136 and 138 which form a part of the undisturbed pilot guide surface 30. The path of the string mills 88 and 90 will have been controlled by the inclined trajectory of the pilot mill 34 so that a central guide surface segment 140 will not have been contacted or will have been contacted in controlled manner by the string mills and will thus remain either at its original geometry or a predetermined geometry. After the casing window milling operation has been completed other well tools, such as those for drilling, lining, cementing and completing and otherwise constructing the lateral branch, will be guided by the original guide surface segment 140 of the guide surface 30 through the casing window and into the lateral branch.

It is considered within the scope of the present invention to provide for guiding of the pilot mill during its initial milling by a generally tubular guide section of the

deflecting tool as discussed above in connection with Figs. 1-13, as shown in Figs. 14-19, and to also provide for guiding of the rotary motor and stabilizer within the deflecting tool rather than in the well casing. This feature can enable the milling tool to be of more compact design as compared with convention milling tool design and  
5 can enable the milling system to accomplish milling of a casing window and tool guide surface of predictable dimension and configuration. It is also considered within the spirit and scope of the present invention to provide the deflecting tool with a specific geometry enabling the deflecting tool and the milling tool to be run into the well casing as a unit and enabling the deflecting tool and the milling tool to be  
10 extracted from the well casing as a unit when a window milling operation has been completed.

Referring now to Figs. 14-19, an alternative embodiment of the present invention is shown generally at 150 which accomplishes the above features. Within the well casing 152 is set a deflecting tool 154 which is located and oriented in any suitable  
15 manner as discussed above. The deflecting tool 154 defines an elongate generally tubular section 156 defining an internal guide surface or passage 158 of generally circular cross-section which is of inclined and slightly curved configuration and which intersects the outer periphery 160 of the deflecting tool in a manner defining a lateral guide opening 162. The lateral guide opening 162, the deflecting tool 154 defines a  
20 generally tubular pilot guide section 166 which is slightly offset with respect to the internal guide surface 158 and defines a generally cylindrical internal pilot guide surface 168 within which the pilot mill 34 is located at the beginning of window milling as shown in Fig. 14 to insure proper location of the milling tool 14 when window milling is initiated, thus insuring that the pilot mill 34 is precisely oriented by  
25 the internal generally cylindrical guide surface 168 the deflecting tool 154 defines an end flange 170 defining a transverse shoulder 173 and forming a guide opening 174. When casing window milling is initiated, a trailing shoulder 177 of a rotary drive motor 110 is normally in engagement with the transverse shoulder 173. This feature permits the deflecting tool 154 to be supported by the milling tool system 14 as the

deflecting tool and milling tool are run into the casing as a unit. Alternatively, and as described above, the pilot mill 34 may be temporarily secured within the pilot mill guide surface 168 by shear screws as described above or by any other suitable means for retention and release. The internal opening 174 of the end flange 170 to pass  
5 through the end flange as window milling operations progress, as shown in Fig. 15. The end flange 170 also facilitates extraction of the milling tool and the deflecting tool as a unit when milling operations have been completed. As the drill stem 180 is withdrawn upon completion of casing window milling the end shoulder 176 of the rotary drive motor 178 will eventually come into contact with the transverse shoulder  
10 173 of the deflecting tool 154. Thereafter, further extracting movement of the drill stem 180 will also accomplish extraction of the deflecting tool 154. It should also be born in mind that the deflecting tool 154, if intended to remain within the well casing as a subsequent guide for well tools from the main well bore into the lateral bore, the end flange 170 may be eliminated. In this case the deflecting tool 154 will be  
15 designed with a "pulling geometry" which will enable its subsequent extraction from the well casing to be accomplished by any suitable pulling equipment. Since the resulting guiding geometry of the deflecting tool 154 will be predictable, the pulling geometry of the deflecting tool is also precisely controlled.

The cross-sectional geometry of the deflecting tool 154 is rendered more evident from  
20 Figs. 17, 18 and 19. As shown in Fig. 17, the internal cylindrical surface 168 is inclined to establish the desired inclination of the pilot bore that is milled by the pilot mill and has an internal diameter shown at 182 within which the outer diameter of the pilot mill 34 is closely fitted. It should be born in mind that the pilot mill 34 is oriented by the internal pilot mill guide surface 168 only at the initial stage of casing  
25 window milling. After the trailing end of the pilot mill has cleared the internal cylindrical guide surface 168, the pilot mill will maintain its angulated orientation relative to the main well bore by that portion of the guide surface of the deflecting tool which is located forwardly of the pilot mill guide surface 168. Also, since the pilot mill 34 is of cylindrical configuration and is provided with a milling surface only at its

leading end, the cylindrical outer periphery of the pilot mill will maintain the orientation that has been pre-established by the pilot mill guide surface 168.

The cross-sectional illustration of Fig. 18 shows a partially tubular internal guide surface being an extension of the internal guide surface 158 of the deflecting tool and  
5 having an internal diameter 184 greater than the internal diameter 182 of the guide surface 168 shown in Fig. 17. This greater internal diameter is sufficient to establish guiding relation with the rotary drive motor and/or the stabilizer element 112 which is connected to the rotary drive motor 110.

As shown in the sectional view of Fig. 19, the end flange 170 of the deflecting tool  
10 154 is defined by opposed flange sections 171 and 172.

As mentioned above, casing milling is initiated with the milling tool 14 shown positioned as in Fig. 14 with the pilot mill 34 disposed in guided relation with the internal cylindrical guide surface 168. As the milling tool 14 is moved forwardly by movement of the drill stem 180 the drill stem will be guided by the cylindrical surface  
15 sections of the flange sections 171 and 172 that define the end flange 170. As this movement occurs the first string mill 88, which may also be referred to as a gaging mill, begins to remove the pilot mill guide section 166 of the deflecting tool. After the second or reaming mill 90 of the elongate milling shaft 110 has passed through the pilot mill guide section of the deflecting tool, the upper portion of the pilot mill guide  
20 section will have been removed, leaving a guide passage essentially being an extension of the internal guide surface 158 of the deflecting tool 154. Consequently as the rotary drive motor 110 and its stabilizer 112 are moved along the internal guide surface 158 efficient positioning of the rigid milling shaft 162 will be maintained thus causing its string mills 88 and 90 to continue milling an inclined, slightly curved guide  
25 passage along the intended trajectory that is desired for the lateral bore. Thus, the rigid milling shaft, being pivotally connected to the pilot mill 34 and to the rotary drive motor 110 will be precisely controlled as it follows its intended milling

trajectory. The deflecting tool 154 will be milled in controlled fashion to effectively form the inclined guide surface 158. The result is that the casing window is milled to precision location, orientation and geometry during casing window milling. Additionally, the dimension of the bore that is milled by the milling tool will be  
5 closely controlled so that wandering of the milling tool is minimized during the milling operation. The net result is predictable and controlled window milling which insures that the deflecting tool achieves a predictable configuration as the result of the milling operation so that it can function efficiently as a tool guide and can be efficiently extracted from the well casing when its use is no longer needed.

10 Referring now to Figs. 20 and 21 a further alternative embodiment of the casing window milling system of the present invention is shown in longitudinal section generally at 190. As mentioned above, it is desirable that the pilot mill, when casing window milling is initiated, be freely pivotal for articulation or angular misalignment relative to the longitudinal axis of the milling shaft to permit efficient guiding of the  
15 pilot mill along the inclined guide surface of the deflecting tool. After the pilot mill has moved free of the tubular guide bearing of the deflecting tool and has moved along the inclined guide surface of the deflector to an extent that self guiding of the pilot mill can no longer be assured, it is desirable to control the articulating mechanism of the pilot mill and milling shaft rotary drive connection so that the  
20 degree of articulation is limited or minimized to permit the trajectory of the pilot mill to be controlled jointly by the deflecting tool and the milling shaft. This feature prevents unconsolidated formations from permitting or causing the pilot mill to be diverted from its intended trajectory.

The embodiment of Figs. 20 and 21 illustrate the articulating connection between a  
25 pilot mill shown generally at 192 and a substantially rigid milling shaft shown generally at 194, wherein the pilot mill is enabled for substantially free articulation relative to the milling shaft when in the condition shown in Fig. 20 and is maintained in substantially coaxial relation with the milling shaft when in the condition shown in

Fig. 21. The pilot mill 192 has a generally circular pilot head 196 to which is fixed or secured a generally cylindrical stabilizing sleeve 198 which defines external grooves 200 and lands 202 to permit the flow of fluid externally of the pilot mill for purposes of cooling and for removal of mill cuttings and other debris. The pilot head 196 defines a milling face 204 and also defines one or more fluid distribution passages 206 through which milling fluid is conducted from an internal fluid chamber 208 to the milling face 204. Although the milling face 204 is shown to be of planar configuration in Figs. 20 and 21 it should be born in mind that it may be of tapered configuration, essentially as shown at 76 in Fig. 11 or it may be rounded or of any other suitable milling face configuration. The outer peripheral lands 202 of the generally cylindrical stabilizing sleeve 198 served to stabilize rotation of the pilot mill as it is rotatably driven by the generally rigid milling shaft 194. This feature enables the pilot mill to be efficiently guided by the inclined guide face 210 of a deflection body 212 that is set within the well casing. Preferably the deflecting body 212 is of the configuration and function shown at 18 in Figs. 1, 2, and 3 and described in detail above.

The generally cylindrical stabilizing sleeve 198 is of tubular configuration and defines a generally cylindrical internal chamber which is formed by internal cylindrical surface segments 214 and 216. The cylindrical surface segment 214 is of slightly larger diameter as compared with cylindrical surface segment 216 and at the juncture of these surface segments is defined an internal circular shoulder 218. A tubular bushing support housing 220 is fixed within the cylindrical surface segment 214 of the internal chamber of the pilot mill 192 with a circular shoulder 222 thereof being located in abutment with the internal circular shoulder 218 of the stabilizing sleeve 198. The pilot head 196 and the bushing support housing 220 define the internal chamber 208. The bushing support housing 220 provides for location of articulation bushings 224 and 226 which cooperatively define a generally spherical internal chamber 228 which receives a spherical end member 230 of the milling shaft 194, thus permitting articulation of the milling shaft in pivotal relation about a pivot point

"P" and within an authorized angle of mis-alignment shown by angle "A" relative to the axial center-line "C" of the milling shaft 194.

The milling shaft 194 defines an end section 232 which tapers from a milling shaft diameter "D" shown in Fig. 21 so that the end section 232 is of smaller diameter as compared to the diameter of the milling shaft. This smaller diameter assists in the amplitude of authorized mis-alignment of the pilot mill relative to the milling shaft. The spherical end member 230 is located at the terminal end of the milling shaft end section 232 so that the pilot mill 192 is freely pivotal about pivot point "P" and thus can be positioned by the deflector guide surface 210 to provide essentially for steering of the milling shaft 194 along an exit angle for casing window milling as determined by the angle of the guide surface 210 of the deflecting body 212.

According to the embodiment shown in Figs. 20 and 21 it is appropriate to permit articulation of the pilot mill relative to the generally rigid milling shaft 194 for the purpose of self steering of the pilot mill by its guided and stabilized contact with the inclined guide surface 210. The steering and rotational stability of the pilot mill 192 is initially achieved by the generally tubular guide bearing of the deflecting body 18 which is shown at 34 in Figs. 1 and 3. When the deflecting element is of elongate, tubular configuration as shown at 154 in Fig. 16, the tubular guide bearing for the pilot mill will be as shown at 166. This guide bearing establishes precision orientation and rotational stabilization of the pilot mill along the exit angle defined by the deflecting member so that a precision pilot window opening will be milled in the well casing at the initial stage of casing window milling as discussed above in connection with Figs. 1 - 19. Thus it is intended to be understood that the pilot mill 192 shown in Figs. 20 and 21 will be initially guided and stabilized in the same manner and for the same purpose as discussed above.

According to Figs. 20 and 21, and as stated above, it is desirable that the pilot mill 192 have freedom of articulation relative to the milling shaft 194 under conditions of

initial casing window milling and that the pilot mill have the capability of being maintained in substantially coaxial relation with the milling shaft when desired so that straight milling along the intended trajectory from the casing window can be readily controlled. To accomplish this feature, the end section 232 of the milling shaft 194 is provided with a circular locking flange or enlargement 234. A tubular locking piston 236 is located within the internal chamber of the stabilizing sleeve 198 and is sealed with respect to an internal cylindrical surface 238 by a circular sealing element 240 and sealed with respect to an external cylindrical surface 242 of a tubular extension 244 of the bushing support housing 220 by a circular sealing element 246. The locking piston 236 functions cooperatively with the tubular bushing support housing 220 and its tubular extension 244 and with the internal cylindrical surface 238 of the stabilizing sleeve 198 to define a hydraulic chamber 248. In the freely pivotal condition of the pilot mill 192 relative to the milling shaft 194 shown in Fig. 20, the hydraulic chamber 248 will be filled with hydraulic fluid which is introduced into the hydraulic chamber through one or more hydraulic fluid passages 250 which are in communication with one or more hydraulic fluid passages 252 that are formed in the circular pilot head 196. The hydraulic fluid passage or passages 252 is normally closed by a frangible closure element 254 shown in Fig. 20. This frangible closure element maintains the hydraulic fluid within the hydraulic fluid chamber 248 and thus prevents movement of the locking piston 236 so that the locking piston remains in the position shown in Fig. 20 with its internal locking surface 256 in axially displaced relation with the circular locking flange 234 of the milling shaft end section 232. A tension spring 258 is located within the internal chamber defined by the stabilizing sleeve 198 of the pilot mill 192 with one of its ends 260 and retained relation with a cylindrical shoulder 262 of the bushing support housing 220. The opposite end 264 of the tension spring 258 is fixed within spring grooves defined by a circular shoulder 266 of the locking piston 236. In the relaxed condition of the tension spring as shown in Fig. 21, the locking piston 236 will be positioned with its internal locking surface 256 in registry with the circular locking flange 234 of the milling shaft. In this condition the pilot mill 192 is secured by the locking piston against articulation

relative to the milling shaft. In this condition the longitudinal axes of the milling shaft and the pilot mill will be in coincidence and therefore the pilot mill will mill a straight course that is in alignment with the longitudinal axis of the milling shaft.

When casing window milling is initiated and during milling of a pilot window  
5 opening in the well casing it is desirable that the pilot mill 192 be disposed in articulating relation with the milling shaft so that the pilot mill is efficiently guided by the inclined guide surface 210 of the deflecting body 212. As long as the frangible closure member 254 remains intact, the hydraulic fluid that is present within the hydraulic chamber 248 will maintain the locking piston positioned as shown in Fig.  
10 20, thus permitting articulation of the pilot mill about the spherical end member 230 of the milling shaft. When it is desired to lock the pilot mill in non-articulating or coaxial relation with the milling shaft the frangible closure 254 is broken away, thereby permitting the tension spring force of the locking piston to discharge some of the hydraulic fluid from the hydraulic chamber 248 through the passages 250 and 252  
15 and through the opening 266. When this occurs, the tension spring 258 will shift the locking piston 236 from the unlocking position of Fig. 20 to the locking position of Fig. 21. Thus, the frangible closure 254 functions as a "locking trigger" that can be actuated in any suitable manner to release hydraulic chamber 248. The locking trigger may be actuated mechanically simply by moving the pilot mill into contact with  
20 certain deflector structure or with casing or formation structure, depending upon the configuration thereof. As the pilot mill is moved along the inclined guide surface of the deflection body so that the center of the milling head of the pilot mill is in registry with the casing, the frangible closure will be broken away by contact with the casing, releasing the hydraulic fluid from the chamber 248 and allowing spring urged  
25 movement of the locking piston 236 to the Fig. 21 position. Alternatively, the locking trigger may conveniently take the form of a pressure responsive closure, thereby permitting it actuation responsive to conditions of downhole fluid pressure. As a further alternative, the locking trigger may take the form of a valve closure that may

be selectively opened by an on-board valve actuator responsive to any suitable fluid telemetry signals.

In a further alternative embodiment, shown in Fig. 22, the inclined contoured guide surface 30 does not extend to the periphery of the deflecting tool at its lower end.  
5 Thus, the deflecting tool 12 defines a bearing surface 300 at the lower end of the guide surface 30 that extends from the lower end of the guide surface 30 to the periphery of the deflecting tool 12. The guide surface 30 is preferably slightly convexly arcuate.

In this embodiment, the intent is to mill the window in the casing, then remove the milling tool 14 and deflecting tool 12 from the well and to use a drilling deflector and  
10 drilling tool to complete the drilling of the lateral. At least a portion of the milling tool 14 remains within the casing when using the embodiment of Fig. 22. Thus, the guide surface 30 of the deflecting tool 12 defines a milling path that limits the travel of the milling tool to substantially prevent the milling tool from exiting the well casing. The bearing surface 300 provides a stop to define the bottom of the milled  
15 window and to stop further milling by the milling tool 14. The convexly arcuate milling surface 30 forces the pilot mill 34 out through the casing initially at a relatively higher rate. Then, once the pilot mill (or the string mills) is at the desired position offset from the centerline of the casing to mill the window of the desired width, such as when the center and widest diameter of the pilot mill 34 (or string  
20 mills) is aligned with the casing, the milling surface 34 directs the pilot mill downward along a milling path that is parallel to the centerline of the casing or along a similar path intended to maintain the desired milling width of the pilot mill 34 and the trailing string mills. Thereby, the arcuate milling surface 34 facilitates milling of a window having a width that has the desired width along a longer length than if the  
25 milling surface 30 were straight, or linear. In one embodiment, the centerline of the pilot mill 34 remains within the periphery of the well casing.

One advantage to maintaining the milling tool 14 at least partially within the casing is that the direction and orientation of the pilot mill is maintained and the pilot mill 34 is substantially prevented from travelling sideways. Prior efforts that have a guide surface 30 that extends to the periphery of the deflecting tool 12 force the mill further through the casing reducing the aligning support offered by the casing. However, the present invention maintains relatively more of the mill in the casing so that the casing provides guiding support to the mill and reduces walk-away suffered by prior milling designs. Walk-away, a problem known in the art to be associated with prior designs, in which the torque of the mill causes the mill to travel radially as well as axially, produces a window in which the centerline of the milled window is not aligned with the axial direction of the borehole. For example, one common problem resulting from walk-away is that the bottom of the milled window is offset from the centerline of the main portion window through which the lateral is accessed. Such a window may affect reentry because many prior designs use the bottom of the milled window to hang reentry tools. If the bottom of the window is offset from the main portion of the window, the orientation of the reentry tool may be incorrect and prevent effective reentry into the lateral.

Further, the milling tool 14 is adapted and designed for milling steel or other metals or materials forming the casing, not for drilling in a formation necessarily. Thus, drilling tools are better suited for drilling the lateral in the formation once the window is formed in the casing. Accordingly, using the embodiment shown in Fig. 22, in which the milling tool 14 remains at least partially within the casing, the milling tool 14 is used for its optimal purpose (milling a window in the casing) and drilling tools are then used to form the lateral. The resulting milled window using this embodiment builds a side pocket suitable for further construction of the lateral.

Additionally, using the embodiment shown in Fig. 22, produces a window 302 having the general shape as shown in Fig. 23. As discussed, the width of the window 302 widens relatively rapidly at its top and then stabilizes at the desired width. Further,

the pilot mill 34 mills a bottom narrow portion 304. The narrow portion 304 is relatively narrow as compared to the portion of the milled window 302 adjacent the narrow portion 304. The narrow portion may be useful for attaching equipment to the casing, such as liners, liner hangers, and other completion or downhole equipment.

5 Additionally, the bottom of the resulting milled window 302 is relatively flat as compared to those milled using the embodiment shown in Fig. 3 for example. The relatively flatter bottom also facilitates use of the casing for attachment of other components.

10 Alternative Embodiment of the Pilot Mill including Core Breaking Mechanism

An alternative embodiment of the pilot mill 34 is shown in Figures 24 and 25. In many milling applications, the center of the relevant mill has a velocity of zero relative to the surface to be milled. This creates unfavorable cutting conditions, often resulting in the destruction of the central portion of the mill and the interruption of the

15 milling process. The illustrated embodiment of pilot mill 34 solves this problem and increases the rate of penetration and durability of the mill in the casing as well as the possibility of milling a window using only one trip of the drill string.

In this embodiment, pilot mill 34 includes a core breaking mechanism 498 that

20 preferably comprises a core passage 500 and a breaking mechanism 502. Core passage 500 extends from the mill nose 78 to the outer guided periphery 36 of the pilot mill 34. Preferably, core passage 500 is included entirely within mill head structure 35. Breaking mechanism 502 is located within core passage 500 and is adapted to break up solid pieces that travel through core passage 500. In the preferred

25 embodiment, breaking mechanism 502 comprises a diverting slope 504 within core passage 500. The diverting slope 504 diverts the core passage 500 from being substantially parallel to the axis of rotation of pilot mill 34 to being directed generally towards the outer guided periphery 36 of pilot mill 34. In the preferred embodiment, diverting slope 504 is constructed from a material that is substantially harder than the

material to be milled. Preferably, diverting slope 504 is hardfaced with carbide or another suitable material.

Core passage 500 can have a variety of configurations, so long as the passage 500 provides communication between the mill nose 78 and the outer guided periphery 36. In the embodiment shown in Figure 24, core passage 500 comprises a core opening 506 having a first end 508 at mill nose 78 and a second end 510 at the outer guided periphery 36. Alternatively and as shown in Figure 25, core passage 500 comprises a core channel 512 that is open to the tapered milling face 76.

10

The core passage 500 is preferably configured on mill head structure 35 so that it does not interfere with the operation of the fluid circulation passages 80 or the fluid supply manifold passage 82. The embodiment shown in Figure 26 shows five fluid circulation passages 80 and the core passage 500 functioning independently from each other.

15

In the preferred embodiment, the core passage 500 extends from mill nose 78 to outer guided periphery 36 in an arcuate radial path. Figure 26 clearly shows that core passage 500 does not extend linearly from mill nose 78 to outer guided periphery 36. Instead, the core passage 500 follows an arcuate path along the radial direction from mill nose 78 to outer guided periphery 36. Also preferably, the curve of the radial arcuate shape of core passage 500 extends in the direction of rotation of pilot mill 34.

20

In operation, the rotating pilot mill 34 is moved towards the appropriate surface. The abrasive inserts on the pilot mill tapered milling surface 76 begin milling the surface. The presence of core passage 500 on mill nose 78 creates a core of non-milled surface that is received within core passage 500 as pilot mill 34 continues the milling process. The core of non-milled surface grows in length within core passage 500 until it hits diverting slope 504. Diverting slope 504 acts to continuously break the core of non-milled surface into pieces as the core is fed through the core passage 500. The broken-

30

up core of non-milled surface is then expelled through the outer guided periphery 36 end of the core passage 500, at which point it joins the remainder of the debris that results from the milling operation.

5    Alternative Embodiment of the Unitary or Integrated Assembly for Deployment Purposes

10    Figures 3, 6, and 7 illustrate one embodiment of the casing window milling assembly 10 in which the deflecting tool 12 is attached to the milling tool 14 during the downhole deployment process. This embodiment includes releasable fasteners such as shear screws 113 and 114 in the tubular guide bearing 32 so as to resist both rotary and linear motion of the pilot mill 34 and the milling shaft 62 relative to the deflecting tool 12.

15    Figures 27 and 28 illustrate an alternative embodiment of a unitary or integral casing window milling assembly 10. This embodiment includes a first retaining mechanism 600, a second retaining mechanism 602, and preferably a protection mechanism 604. In this embodiment, pilot mill 34 is preferably secured at least partially within guide bearing 32.

20    First retaining mechanism 600 is attached to the drift guide surface 33 so that it is adjacent the pilot mill rear end 606. In the preferred embodiment, first retaining mechanism 600 comprises a first retaining member 608 (Figure 28) that is securely attached to the drift guide surface 33, such as by threading, welding, or by other means  
25    known in the art. First retaining member 608 is shown in Figure 28 as having a ring shape, although first retaining member 608 can have any shape (such as a half ring or an arcuate segment) provided that first retaining member 608 supports pilot mill 34 in place. In another embodiment as shown in Figure 27, first retaining mechanism 600 comprises at least one securing screw 610 that is inserted through tubular guide

bearing 32 so that it protrudes from drift guide surface 33 next to pilot mill rear end 606.

5 Second retaining mechanism 602 is attached to the drift guide surface 33 or the inclined guide surface 30 so that it is adjacent the pilot mill front end 612. In the preferred embodiment, second retaining mechanism 602 comprises a second retaining member 614 that is securely attached to the drift guide surface 33 or the inclined guide surface 30, such as by threading, welding, or by other means known in the art. Second retaining member 614 is shown in Figures 27 and 28 as having a general ring shape, 10 although second retaining member 614 can have any shape (such as a half ring, a disc, or a half disc) provided that second retaining member 614 supports pilot mill 34 in place. In one embodiment and as shown in the Figures, the second retaining member rear end 620 mirrors the tapered shape of tapered milling face 76.

15 Protection mechanism 604 is located intermediate the pilot mill 34 (pilot mill front end 612) and the second retaining mechanism 602. Protection mechanism 604 protects the abrasive inserts of pilot mill 34 which are included on tapered milling face 76 from hitting the second retaining member rear end 620 during the deployment process. In one embodiment as shown in Figure 27, protection mechanism 604 20 comprises a protection screw 622 that is embedded in tapered milling face 76 (or pilot mill front end 612). Protection screw 622 includes a screw head 624 that extends farther from pilot mill front end 612 than the abrasive inserts of pilot mill 34. Screw head 624 is adjacent second retaining member 620. In another embodiment as shown in Figure 28, protection mechanism 604 comprises a resilient member 626 that is 25 disposed intermediate tapered milling surface 76 (and abrasive inserts) and second retaining member rear end 620. Resilient member 626 is constructed from a resilient material such as rubber. In the preferred embodiment and as shown in Figure 33, resilient member 626 includes a plurality of cuts or serrations 710 extending from the center portion 712 preferably to the outer circumference 714 of the resilient member

626. Cuts 710 also preferably extend axially through the resilient member 626 and are spaced about the center portion 712.

5 In operation, casing window milling assembly 10 is deployed downhole with the pilot mill 34 secured to the drift guide surface 33 and/or the inclined guide surface 30 by use of the first retaining mechanism 600, the second retaining mechanism 602, and the protection mechanism 604. First retaining member 608 aids in maintaining pilot mill 34 in its proper place, supports the load of pilot mill 34 as the casing milling assembly 10 is deployed downhole, and reacts forces applied to pilot mill 34 that are in the  
10 downward direction. Second retaining member 614 aids in maintaining pilot mill 34 in its proper place and reacts forces applied to pilot mill 34 that are in the upward direction. Protection mechanism 604 protects the abrasive inserts of tapered milling face 76. If the casing window milling assembly 10 is jarred during the deployment process, pilot mill 34 tends to be forced against second retaining member 614 which  
15 event would damage the abrasive inserts, if not for the presence of protection mechanism 604. Protection mechanism 604 absorbs the force caused by the jarring event and thus prevents the abrasive inserts from being damaged. In the embodiment including the protection screw 622, protection screw 622 absorbs the jarring force since the screw head 624 extends farther from the pilot mill front end 612 than the  
20 abrasive inserts. In the embodiment including resilient member 626, resilient member 626 absorbs the jarring force due to its resilient material construction.

After the deflecting tool 12 has been properly oriented and set within the well casing, the milling operation may be initiated by applying sufficient rotational force to the  
25 pilot mill 34. The rotation of the pilot mill 34 causes the general disintegration of first retaining mechanism 600, second retaining mechanism 602, and protection mechanism 604. Thus, the elements that comprise first retaining mechanism 600, second retaining mechanism 602, and protection mechanism 604 are constructed from materials that can be easily milled by pilot mill 34 and string mills 88 and 90.  
30 Adequate materials include steel and aluminum, and rubber for resilient member 626.

In the embodiment including resilient member 626 with cuts 710, the cuts 710 weaken resilient member 626 in the direction of rotation enabling the efficient disintegration of the resilient member 626. Once first retaining mechanism 600, second retaining mechanism 602, and protection mechanism 604 are disintegrated, the milling  
5 operation continues as previously disclosed.

In another embodiment as shown in Figure 29, second retaining mechanism 602 comprises a plug 630 that extends from adjacent the pilot mill front end 612 (or proximate the uphole end of the deflecting tool 12) towards the downhole end of  
10 deflecting tool 12. Preferably, plug 630 substantially fills the entire area or volume that is at least partially defined by inclined guide surface 30. Plug 630 preferably completes the outer cylindrical shape of deflecting tool 12. Plug 630 is constructed from a material that can be easily milled by pilot mill 34 and string mills 88 and 90, such as a plastic or soft steel, or a combination thereof. Cement may also be used to  
15 construct plug 630.

In addition to the utility described above (as second retaining mechanism 602), plug 630 also improves the efficiency, control, and reliability of the initial phase of the milling operation. First, milling operations are more controllable and predictable if  
20 the entire or substantially the entire milling face of the mill is in contact with a millable surface. Second, the fact that the entire or substantially the entire milling face of the mill is in contact with a millable surface also provides continuous cooling of the pilot mill 34 by providing a continuous flow of debris and fluid through channels 40.

25

In addition, the fact that the entire or substantially the entire milling face of the mill is in contact with a millable surface from the start of the milling operation enables a greater amount of cuttings to be removed from the downhole environment, as compared to prior art mills. In prior art designs, the deflecting tool 12 does not  
30 include a plug 630. Thus, during the initial stages of the milling operation, only a

portion of the milling face contacts a millable surface (the target casing), allowing a large number of cuttings to fall down the wellbore and/or be forced down the wellbore by hydraulic fluid jetting from the mill. Many of the cuttings that fall lodge proximate the downhole end of the deflecting tool 12 (or possibly farther down) and become an  
5 obstruction that must be removed prior to the commencement of post-milling operations. Such removal is typically performed at a high cost.

After the deflecting tool 12 has been properly oriented and set within the well casing, the milling operation may be initiated by applying sufficient rotational force to the  
10 pilot mill 34. The rotational motion disintegrates first retaining mechanism 600 and protection mechanism 604. The pilot mill 34 then begins to mill plug 630. At first, the milling face of pilot mill 34 contacts and mills plug 630. As pilot mill 34 moves along inclined guide surface 30, at least a section of the pilot mill 34 contacts the target casing so that the milling face mills both the target casing and the plug 630.  
15 After some time, the pilot mill 34 may also contact the formation adjacent the target casing. Thus, at all times, the entire or substantially the entire surface of the milling face is in contact with a millable material (either the formation, the casing wall or the plug 630) thereby enabling the additional utilities disclosed in the previous paragraphs.

20

In particular, since at least substantially the entire milling face of pilot mill 34 contacts a millable material at all times, very few of the cuttings are allowed to fall down the wellbore. Instead, the majority of the cuttings are forced to pass through the channels 40 and out of the downhole environment. Initial tests have shown a substantial  
25 increase in the weight of cuttings removed from the wellbore with use of the plug 630, as compared to milling systems that do not include a plug (or the like).

For purposes of clarity, the term “substantially” in “substantially the entire face of the mill” is defined to be at least 50% of the milling face of the mill. Preferably, at least 75% of the milling face is in contact with a millable surface. In the most preferred embodiment, at least 90% of the milling face of the mill is in contact with a millable surface. In this most preferred embodiment, the entire milling face of the mill is preferably in contact with a millable surface (plug 630, casing wall, or formation), except when the milling face encounters/crosses the gap between the target casing and the deflecting tool 12. The size of the gap is at least partially governed by the drift diameter of the casing.

10

The plug 630 may also be used with downhole tools other than a deflecting tool, such as packers, plugs, or debris barriers. Any tool that may have to be milled while located in the downhole environment would benefit from the inclusion of plug 630. In these cases, plug 630 would fill in gaps or empty areas of the tool thereby ensuring that the entire or substantially the entire milling face of the milling tool contacts a millable surface (and not empty space) during the subsequent milling operation of the downhole tool. Plug 630 may comprise, in this embodiment, a plurality of independent sections, each section filling in a different gap or empty area of the tool.

Although the plug 630 has been described in association with a milling tool and milling operation, it is understood that the plug 630 may also be used with a drilling tool and drilling operation. No modifications would need to be made in order to use the plug 630 in a drilling operation, other than perhaps ensuring that plug 630 is constructed from a material that can be easily drilled by a drilling tool, such materials being known in the art.

In addition, it is also understood that the plug 630 may be used with any deflecting tool and not only with the particular deflecting tool depicted in Figure 22 or in the

remainder of this application. For example, plug 630 may be used with deflecting tools that include an inclined contoured guide surface that extends to the periphery of the deflecting tool at its lower end and with deflecting tools that do not have a bearing surface (like bearing surface 300 of Figure 22) at the lower end of the guide surface.

5 And, plug 630 may also be used with deflecting tools that do not include an attachment mechanism for the milling or drilling tool, wherein the deflecting tool is run into the hole separately from the milling or drilling tool. Furthermore, plug 630 may be used with deflecting tools having inclined guide surfaces of any angle.

Also in the preferred embodiment, the portion of guide bearing 32 that is milled away

10 during the milling process is constructed from a material that is softer than the material that comprises the remainder of the deflecting tool 12. In the preferred embodiment, such a portion of guide bearing 32 is annealed prior to use.

#### Retrievability of Deflecting Tool

15

Once the milling operation is concluded, a retrieving tool 650 may be inserted into the wellbore to retrieve deflecting tool 12. The interconnection between retrieving tool 650 and deflecting tool 12 is illustrated in Figures 30 and 31. It is noted that the deflecting tool 12 shown in Figure 30 is hollow, unlike the deflecting tools 12 shown

20 in the prior figures. Whether deflecting tool 12 is hollow or not is not critical for the purposes of this invention and either embodiment is encompassed thereby.

Deflecting tool 12 includes a slot 652 preferably defined on inclined guide surface 30. Slot 652 includes a main section 654, preferably rectangular in shape, and a wedge

25 section 656. In the preferred embodiment, wedge section 656 is proximate the uphole end of deflecting tool 12 so that the wide end 658 of wedge section 656 is proximate main section 654 and the narrow end 660 of wedge section 656 is distal thereto. In those embodiments in which deflecting tool 12 is not hollow, slot 652 should extend from the inclined guide surface 30 to the outer surface of the deflecting tool 12.

Retrieving tool 650 includes a hook member 662 extending therefrom. In the preferred embodiment, hook member 662 is selectively removable from retrieving tool 650. The selective removability of the hook member 662 is enabled by any  
5 means known in the art, such as fasteners to retrieving tool 650 or a tongue and groove system with a lock. The removability of hook member 662 facilitates the transportation and cleaning, among others, of the hook member 662.

Hook member 662 comprises a first section 664 and a second section 666. First  
10 section 664 extends from retrieving tool 650, preferably radially therefrom, towards second section 666. Second section 666 is connected to first section 664, preferably distal to deflecting tool 12. Hook member 662 is sized and constructed so that it may be selectively inserted into slot 652. Thus, in the preferred embodiment, the longest  
15 portion of hook member 662 is not longer than the longest portion of main section 654, and the widest portion of hook member 662 is not wider than the widest portion of main section 654.

Second section 666 includes a ramping surface 668 that preferably faces the deflecting tool 12 and is proximate the uphole end of deflecting tool 12. Preferably, the ramping  
20 surface uphole end 670 extends past or farther uphole than the first section uphole end 672. Also preferably, the ramping surface side ends 676 extend past or farther laterally than the first section side ends 674. When deflecting tool 12 is properly positioned downhole, the uphole edges 696 of slot main section 654 extend at an angle  $\alpha$  from the casing wall. In addition, when retrieving tool 650 is located  
25 downhole so that the second section distal end 678 (or hook member distal end) abuts the casing wall, ramping surface 668 extends at an angle  $\beta$  from the casing wall. In the preferred embodiment, angle  $\beta$  is greater than angle  $\alpha$ . Furthermore, the retrieving tool 650 is preferably constructed so that the distance between the second section distal end 678 and the retrieving tool side 684 that is laterally opposite the second  
30 section distal end 678 is slightly smaller than the drift diameter of the casing.

Also in the preferred embodiment, first main section 664 is at least partially tapered towards the first section uphole end 672. The taper angle  $\theta$  of first section 664 preferably matches the angle  $\delta$  defined by wedge section 656. It is not necessary, although it is possible, for the length of the first section tapered surfaces 680 to equal the length of the wedge section surfaces 682.

Retrieving tool 650 preferably also includes a cleaning mechanism 686, which may comprise a retrieving tool opening 688 and at least one port 690. Retrieving tool opening 688 is in fluid communication with a cleaning fluid pressurized source at the surface. Each port 690 extends through hook member 662 and provides fluid communication between the retrieving tool opening 688 and the exterior of retrieving tool 650 adjacent second section distal end 678. A jet nozzle 694 is preferably included within each port 690.

15

Figure 32 illustrates an isometric view of retrieving tool 650. Retrieving tool 650 includes a longitudinal axis 700, a first perpendicular axis 702 from longitudinal axis 700, and a second perpendicular axis 704 from longitudinal axis 700. First perpendicular axis 702 extends from longitudinal axis 700 so that a plane including first perpendicular axis 702 and being perpendicular and transverse to longitudinal axis 700 passes through hook member 662. Second perpendicular axis 704 extends from longitudinal axis 700 so that it is perpendicular to first perpendicular axis 702. Retrieving tool 650 is preferably constructed so that the moment of inertia with respect to the second perpendicular axis 704 is substantially greater, and preferably at least three times greater, than the moment of inertia with respect to the first perpendicular axis 702.

25

In operation, once the milling operation has been completed, the retrieving tool 650 is inserted downhole. The cleaning mechanism 686 is activated so that cleaning fluid is

injected from the surface through retrieving tool opening 688 and out through each port 690. The pressure monitored at the fluid pressurized source located at the surface remains constant until the retrieving tool 650 is adjacent the deflecting tool 12. At this point, the monitored pressure will decrease somewhat as the retrieving tool 650  
5 continues along the inclined guide surface 30. This change in pressure alerts the operator that the retrieving tool 650 has reached the deflecting tool 12. The monitored pressure will bottom out when the hook member 662 is adjacent the slot 652 since the flow of cleaning fluid immediately out of ports 690 is not obstructed by the casing wall or the inclined guide surface 30, as before. The large pressure drop indicates to  
10 the operator that the hook member 662 is adjacent the slot 652. The jet nozzles 682 will of course clean the slot 652 as they pass thereby, which enables the proper insertion of hook member 662 therein. At this point, the operator may manipulate the retrieving tool 650 so that hook member 662 is inserted into slot 652. The pressurized fluid flowing out of the pressurized fluid source, through the retrieving  
15 tool opening 688 of the retrieving tool body, and through each port 690 as well as the pressure gauge operatively connected to the retrieving tool opening 688 comprise a hydraulic signature mechanism. The hydraulic signature mechanism enables an operator to monitor the pressure of fluid out of ports 690 and therefore enables an operator to monitor the location of the retrieving tool 650 in relation to the deflecting  
20 tool 12, as previously disclosed.

Figures 30 and 31 illustrate the initial insertion position of the hook member 662 relative to the slot 652. Once this initial insertion is achieved, the operator should begin to slowly retrieve the retrieving tool 650. This motion enables the ramping  
25 surface 668 to contact the uphole edges 696 of slot main section 654. Since second section distal end 678 abuts the casing wall, continued upward motion of the retrieving tool 650 causes the uphole edges 696 of slot main section 654 to ramp or slide on ramping surface 668. And, since the angle  $\beta$  of ramping surface 668 is greater than the angle  $\alpha$  of the uphole edges 696, the continued upward motion of the  
30 retrieving tool 650 causes the uphole end of the deflecting tool 12 to be lifted away

from the segment of casing wall it was previously abutting. This upward motion also results in the first section 664 entering wedge section 656 and the first section tapered surfaces 680 mating with the wedge section surfaces 682. Hook member 662 is thus secured within slot 652 by the interaction between ramping surface 668 and uphole edges 696 and the interaction between first section tapered surfaces 680 and wedge section surfaces 682.

The fact that the uphole end of the deflecting tool 12 is lifted away from the relevant segment of casing wall greatly facilitates the retrieval of the deflecting tool 12. Without such a lifting motion, the uphole end of the deflecting tool 12 can easily jam against a variety of downhole objects, such as collars or debris, during the retrieval process. Further complications arise if the wellbore is deviated and the uphole end of the deflecting tool 12 must maneuver bends in the casing wall. By lifting the uphole end of the deflecting tool 12, the retrieving tool 650 greatly reduces the chances of the deflecting tool 12 jamming during the retrieval process.

Furthermore, the fact that hook member 662 and slot 652 are engaged along the lengths of first section tapered surfaces 680 greatly increases, over the known prior art, the amount of surface area that is in contact between the retrieving tool 650 and the deflecting tool 12. The prior art typically includes a hook and slot combination that are engaged only at the portion corresponding to the wedge section narrow end 660. By increasing the surface area of engagement, a greater amount of lifting load may be applied during the retrieval process. In addition, by engaging the hook member 662 and slot 652 at tapered surfaces, 680 and 682, much less relative movement between the retrieving tool 650 and the deflecting tool 12 is exhibited during the retrieval process.

The fact that the distance between the second section distal end 678 and the retrieving tool side 684 is slightly smaller than the drift diameter of the casing also facilitates the retrieval of deflecting tool 12. If the difference between the two dimensions is

substantial, then there is enough space for the hook member 662 to become disengaged from the slot 652, specially if a jarring event occurs during the retrieval process. On the other hand, even if a jarring event occurs while using retrieving tool 650, the minimal space provided by the relative dimensions of the retrieving tool 650 and the casing drift diameter greatly inhibits, if not abolishes, the chances of disengagement.

Throughout the use of the retrieving tool 650, the hook member 662 may be pressed against the casing wall as shown in Figure 30. Due to the fact that the moment of inertia with respect to the second perpendicular axis 704 is substantially greater, and preferably at least three times greater, than the moment of inertia with respect to the first perpendicular axis 702, the retrieving tool 650 tends to bend about the second perpendicular axis 704. This movement facilitates the insertion of hook member 663 into slot 652 as well as the retrieval of deflecting tool 10.

15

In view of the foregoing it is evident that the present invention is one well adapted to attain all of the objects and features hereinabove set forth, together with other objects and features which are inherent in the apparatus disclosed herein.

As will be readily apparent to those skilled in the art, the present invention may easily be produced in other specific forms without departing from its spirit or essential characteristics. The present embodiment is, therefore, to be considered as merely illustrative and not restrictive, the scope of the invention being indicated by the claims rather than the foregoing description, and all changes which come within the meaning and range of equivalence of the claims are therefore intended to be embraced therein.

CLAIMS

1. A downhole assembly, comprising:  
a deflecting tool adapted for selective static positioning within a wellbore;  
a milling or drilling tool adapted to be guided by the deflecting tool;  
5 the milling or drilling tool including a face;  
the deflecting tool including a plug constructed from a millable or drillable material; and  
at least substantially the entire face of the milling or drilling tool being in contact with the plug during the commencement of the milling or drilling operation.  
10
2. The assembly of claim 1, wherein at least substantially the entire face of the milling or drilling tool is in contact with at least one of the formation, the well casing, or the plug during the operation.
- 15 3. A downhole assembly, comprising:  
a deflecting tool adapted for selective static positioning within a well casing;  
a milling or drilling tool adapted to be guided by the deflecting tool;  
the deflecting tool including a plug and a downhole end;  
the plug constructed from a millable or drillable material; and  
20 the plug located intermediate the downhole end and the milling or drilling tool.
4. The assembly of claim 3, wherein the plug extends from adjacent the front end of the milling or drilling tool towards the downhole end of the deflecting tool.
- 25 5. The assembly of claim 3, wherein:  
the deflecting tool includes an inclined guide surface which guides the milling or drilling tool; and

the plug substantially fills the volume at least partially defined by the inclined guide surface.

6. A deflecting tool for downhole use, comprising:  
5 an uphole end and a downhole end;  
a plug constructed from a millable or drillable material; and  
the plug located intermediate the uphole end and the downhole end.
7. The tool of claim 6, wherein the plug extends from proximate the uphole end  
10 towards the downhole end of the deflecting tool.
8. The tool of claim 6, further comprising:  
an inclined guide surface which deflects downhole tools toward a  
predetermined trajectory; and  
15 the plug substantially filling the volume at least partially defined by the  
inclined guide surface.
9. The tool of claim 8, wherein the plug completes the outer cylindrical shape of  
the deflecting tool.  
20
10. The tool of claim 6, wherein the plug is constructed from soft steel.
11. The tool of claim 6, wherein the plug is constructed from plastic.
- 25 12. The tool of claim 6, wherein the plug is constructed from a combination of soft  
steel and plastic.

13. A method for conducting a milling or drilling operation in a wellbore, comprising:

(a) locating within a well casing a deflecting tool having a plug constructed from a millable or drillable material;

5 (b) positioning within the well casing a milling or drilling tool including a face;

(c) rotating and moving the milling or drilling tool to commence the operation; and

(d) contacting at least substantially the entire face of the milling or drilling  
10 tool with the plug during the commencement of the operation.

14. The method of claim 13, further comprising contacting at least substantially the entire face of the milling or drilling tool with at least one of the formation, the well casing, or the plug during the operation.

15

15. The method of claim 13, wherein:

the deflecting tool includes a downhole end; and

the plug is located intermediate the front end of the milling or drilling tool and the downhole end of the deflecting tool.

20

16. The method of claim 15, wherein the plug extends from adjacent the front end of the milling or drilling tool towards the downhole end of the deflecting tool.

17. The method of claim 13, wherein:

25 the deflecting tool includes an inclined guide surface which guides the milling or drilling tool; and

the plug substantially fills the volume at least partially defined by the inclined guide surface.

18. A method for conducting a milling or drilling operation in a wellbore, comprising:

(a) locating within a well casing a deflecting tool having a plug constructed from a millable or drillable material;

5 (b) positioning within the well casing a milling or drilling tool;

(c) rotating and moving the milling or drilling tool to commence the operation; and

(d) milling or drilling at least a portion of the plug during the commencement of the operation.

10

19. A downhole assembly, comprising:

a downhole tool including a plug constructed from a millable material;

the plug located within and filling in gaps or empty areas of the tool; and

the plug adapted to be milled or drilled while the tool is located in the

15 downhole environment.

20. A method for milling a downhole tool, comprising:

(a) locating within a well a downhole tool having a plug constructed from a millable material;

20 (b) positioning within the well a milling tool;

(c) rotating and moving the milling tool to mill the downhole tool; and

(d) contacting, during the milling operation, at least substantially the entire face of the milling tool with at least one of the plug or the parts of the downhole tool not including the plug.

25

21. The method of claim 20, wherein the plug fills in gaps or empty areas of the downhole tool.

22. A method for milling a window in a well casing, comprising:

- (a) locating within a well casing a deflecting tool having a plug;
  - (b) positioning within the well casing a milling tool;
  - (c) rotating and moving the milling tool to mill a window in the well casing; and
- 5           (d) contacting at least substantially the entire face of the milling tool with the plug during the commencement of the milling operation.

23.   A method for milling a window in a well casing, comprising:
- (a) locating within a well casing a deflecting tool having a plug;
  - 10       (b) positioning within the well casing a milling tool;
  - (c) rotating and moving the milling tool to mill a window in the well casing; and
  - (d) milling at least a portion of the plug during the commencement of the milling operation.
